Abstract

Introduction: Antibiotic prophylaxis has been less extensively studied in plastic surgery and specifications of the ideal duration and types of antibiotics are often not specified. Very few studies have been carried out looking at optimal use of antibiotic prophylaxis and the practice of antibiotic prophylaxis is largely dependent on physician preference and individual knowledge.

Methods: We have formulated four practical questions relevant for the daily plastic surgery practice and evaluated the scientific evidence to formulate answers to these questions using the medical database of the National Library of Medicine (Pubmed.gov®)

• What are the indications for antibiotic prophylaxis in plastic surgery?
• Which organisms are involved in postoperative plastic surgery infections?
• Which prophylactic antibiotics in which dose should be used?
• What is the duration of prophylactic antibiotic use?

Results: A single dose first-generation cephalosporin such as cefazolin or ampicillin-sulbactam shows the lowest infections rate. Antibiotics are indicated in clean plastic surgery procedures with high-risk factors and in clean-contaminated or contaminated procedures. A short-course administration regimen seemed to be of adequate efficacy and safety.

Conclusion: There is an indication for surgical prophylaxis in clean plastic surgery procedures with high-risk factors and in clean-contaminated or contaminated procedures. A short-course administration regimen seemed to be of adequate efficacy and safety. High-quality prospective trials on larger scale are needed to further confirm these findings.

Keywords: Antibiotics; Prophylaxis; Plastic Surgery; Guidelines

Introduction

Antibiotic prophylaxis administered perioperatively has been shown to decrease the risk of post-operative surgical site infection but specifics of use vary widely among different surgical specialties. Antibiotic prophylaxis was instituted in the 1960’s along with the initiation of a wound classification system by the National Research Council in the United States [1]. Since its
Antibiotic prophylaxis has been less extensively studied in plastic surgery and specifications of the ideal duration and types of antibiotics are often not specified.

Very few studies have been carried out looking at optimal use of antibiotic prophylaxis and the practice of antibiotic prophylaxis is largely dependent on physician preference and individual knowledge [1].

We have formulated four practical questions relevant for the daily plastic surgery practice and evaluated the scientific evidence to formulate answers to these questions using the medical database of the National Library of Medicine (Pubmed.gov®)

1. What are the indications for antibiotic prophylaxis in plastic surgery?
2. Which organisms are involved in postoperative plastic surgery infections?
3. Which prophylactic antibiotics in which dose should be used?
4. What is the duration of prophylactic antibiotic use?

Indications for Antibiotic Prophylaxis in Plastic Surgery

Although recommendations for antibiotic prophylaxis exist for cardiac, colorectal, neurosurgical, and orthopedic procedures, national and international guidelines for antibiotic prophylaxis in plastic surgery are lacking. In fact, studies examining the impact of prophylactic antibiotics have produced contradictory results (for example in breast surgery and abdominoplasty surgery).

Most placebo-controlled and retrospective studies for dermatological surgery, abdominoplasty, clean head and neck surgery (radical neck dissection, tumor excision and reconstruction), hand surgery (flexor tendon injuries, carpal tunnel release) and facial procedures (rhinoplasty, facial fractures) have an associated surgical site infection (SSI) rate of <5% (clean wound; class I) and prophylactic antibiotics are not indicated [3-6].

An exception is clean breast surgery (augmentation, reduction and reconstructive, lumpectomy, mastectomy, axillary node dissection) and clean plastic surgeries with high-risk factors (for example breast implants) where systemic antibiotic prophylaxis is recommended [7,8].

Oral procedures, such as wedge excision of lip or ear, flaps on the nose and head and neck flaps, have SSI rates of approximately 5–10% (Class II, clean-contaminated wounds). Antibiotics in class II should be considered [4]. Factors that increase the risk of postoperative infectious complications for plastic surgery procedures include implants, skin irradiation before the procedure, and procedures below the waist. Antibiotics have to be considered in these cases.

Class III (contaminated wounds, mainly hand and head and neck surgery) and Class IV (dirty and infected wounds) should receive antibiotic treatment as antibiotics are therapeutic for these classes [5,7,8].

Organisms Involved in Postoperative Plastic Surgery Infections

The most common organisms in infections after plastic surgery procedures are Staphyloococcus aureus, other staphylooccci, and streptococci. Procedures involving macerated, moist environments (e.g., under a panniculus or axilla of an obese individual), below the waist, or in patients with diabetes are associated with a higher rate of infection with gram-negative organisms such as Pseudomonas aeruginosa, Serratia marcescens, or Enterobacteriaceae (including Escherichia coli), Klebsiella species and Proteus mirabilis [9].

Types of Prophylactic Antibiotics and Dose Recommendation

There is no consensus on the appropriate antimicrobial agent to use for prophylaxis in plastic surgery procedures. Agents with good gram-positive coverage and, depending on the site of surgery, activity against common gram-negative organisms are recommended for patients undergoing clean plastic surgery procedures with risk factors or clean contaminated procedures.

The ideal antibiotic for surgical prophylaxis should (1) cause minimal toxicity or side effects, (2) be effective against the most likely organisms that will cause an SSI but have a narrow spectrum, (3) achieve adequate tissue concentrations at the surgical site for the duration of the procedure, and (4) be administered for the shortest effective period [10,11].

For most patients undergoing plastic surgery procedures, the preferred antimicrobial agent is a first-generation cephalosporin such as cefazolin or ampicillin-sulbactam.
An intravenous dose of 1 gram cefazolin is recommended for patients up to 175 pounds (approximately 80 kg).

If the patient weighs more than 175 pounds, the dose of cefazolin may be increased to 2 grams intravenously and to 3 grams in case of more than 265 pounds (more than 120 kg).

Cefazolin should be administered intravenously 15-60 minutes before the surgery.

An additional dose should be given if the surgical procedure lasts more than three to five hours or if the patient has lost a significant amount of blood (greater than or equal to 1500 mL). Patients with a beta-lactam allergy may receive clindamycin or vancomycin.

Clindamycin should be administered intravenously 15-30 minutes before the surgery with a dose of 600 mg IV. Another dose of 600 mg IV should be given in case of surgeries of more than 4 hours.

Due to their longer half-lives, these medications can be redosed at longer intervals if necessary (clindamycin every four to six hours; vancomycin every six to 12 hours). Vancomycin may be given for surgical prophylaxis in facilities with a high incidence of methicillin-resistant Staphylococcus aureus (MRSA) or methicillin-resistant coagulase-negative staphylococci.

Guidelines recommend against the routine administration of vancomycin for antibiotic prophylaxis [10-13].

**Duration of Antibiotic Treatment**

Antimicrobial prophylaxis should be limited to the shortest duration possible to prevent SSIs (even if a drain or a catheter is left in place or an implant is inserted), limit adverse events, and prevent antimicrobial resistance.

The results of a meta-analysis of 32 studies in head and neck surgery, breast and body surgery and hand surgery were divided into one of four duration categories: no antibiotic prophylaxis, single-dose prophylaxis, 24-hour prophylaxis or extended course (more than 24 hours) prophylaxis. The data was then statistically analyzed for each duration group.

The average percentage of surgical site infections per population for each category was as follows: 14.8% when no prophylaxis was given, 7.7% for a single dose prophylaxis, 14.1% for 24 hours prophylaxis, and 8.8% for an extended course of antibiotics.

However, as the confidence intervals are wide and overlapping, these findings are not statistically significant. A comparison of the data for antibiotic prophylaxis demonstrates a possible decrease in post-operative incidents for the single dose prophylaxis and the extended course of antibiotics in comparison to no antibiotics and a 24-hour course of antibiotics [14].

**Conclusions**

There is an indication for surgical prophylaxis in clean plastic surgery procedures with high-risk factors and in clean-contaminated or contaminated procedures. A short-course administration regimen seemed to be of adequate efficacy and safety. High-quality prospective trials on larger scale are needed to further confirm these findings.
